Risk-Averse Model Predictive Operation Control of Islanded Microgrids

Christian A. Hans®, Student Member, IEEE, Pantelis Sopasakis®, Jörg Raisch®, Carsten Reincke-Collon, and Panagiotis Patrinos®, Member, IEEE

Abstract—In this paper, we present a risk-averse model predictive control (MPC) scheme for the operation of islanded microgrids with very high share of renewable energy sources. The proposed scheme mitigates the effect of errors in the determination of the probability distribution of renewable infeed and load. This allows to use less complex and less accurate forecasting methods and to simulate low-dimensional scenario-based optimization problems, which are suitable for control applications. Additionally, the designer may trade performance for safety by interpolating between the conventional stochastic and worst case MPC formulations. The presented risk-averse MPC problem is formulated as a mixed-integer quadratically constrained quadratic problem and its favorable characteristics are demonstrated in a case study. This includes a sensitivity analysis that illustrates the robustness to load and renewable power prediction errors.

Index Terms—Average value-at-risk (AVaR), energy management, islanded microgrids, model predictive control (MPC), operation control, risk-averse control.

I. INTRODUCTION

The substitution of conventional power plants by renewable energy sources (RES) is a key element in the fight against climate change. However, it presents major challenges. The structure of power supply is expected to change from a small number of large-scale power plants to a large number of small-scale units. These will be geographically distributed over the entire electric grid. Additionally, the uncertainty in power supply of some RES will complicate the operation of the grid.

One way to tackle these challenges is to partition the electric grid into microgrids (MGs) [1]. These comprise storage, conventional, and renewable units connected to each other and to loads by transmission lines [2]. MGs can be operated connected to the grid or electrically isolated (islanded) [3]. Inspired by conventional power systems, hierarchical approaches have been promoted for the control of MGs, e.g., in [4]. On the lower control layer, typically on a timescale from milliseconds to seconds, primary control aims to provide voltage and frequency stability. Secondary control, typically on a timescale from seconds to minutes, aims at compensating frequency deviations and ensures that the voltages remain close to the desired values. Operation control, also referred to as energy management, typically acts on a timescale of minutes to fractions of hours. It aims at optimizing the MG operation by providing power set points to the units [5]. For this task, model predictive control (MPC) approaches are considered a good choice as they allow to explicitly include constraints on the units and take into account the system dynamics. Moreover, they can be combined with forecasts of load and renewable infeed to operate the MG in an optimal way.

A. Operation Control of MG

Several approaches for the operation control of MGs have been proposed. One way to categorize them is by the way they handle uncertainties. Prominent formulations are: 1) certainty equivalent, where a deterministic system model is fully trusted; 2) worst case, where no probability distribution is considered; 3) risk-neutral stochastic, where an underlying probability distribution is trusted; and 4) risk averse, where the underlying distribution is not fully trusted.

There are a variety of publications on operation control of MGs, where a perfect forecast is assumed. For example, in [6], a certainty-equivalent approach for grid-connected MGs is proposed. Based on the assumption that the forecast generation of RES, load, and the energy price is certain, in [7], an MPC is presented. For islanded MGs, an MPC approach that also assumes perfect forecasts is given in [8]. A certainty-equivalent approach that includes power flow over the lines is
proposed in [9]. However, as shown in [10], in the operation of islanded MGs with high share of RES, certainty-equivalent approaches can lead to significant constraint violations.

To compensate for this lack of robustness, some authors have proposed worst case MPC approaches for the operation of MGs. Uncertain parameters, such as model parameters [11] and forecasts [10], [12], are treated as bounded quantities and an MPC formulation is used to minimize the worst case cost. The MPC approaches for islanded MGs in [10] and [12] include power flow over the lines, power sharing of grid-forming units, and curtailable renewable infeed. However, these approaches have been found to be overly conservative as they try to minimize the worst case objective [10], [12].

The conservativeness of worst case approaches has led to the wide adoption of stochastic methods, which consist in minimizing the expected value of a random cost with respect to an assumed probability distribution. There are two main approaches to modeling randomness: 1) random processes with continuous distributions and 2) scenario trees.

In the area of MG control, some authors have used the assumption that all involved uncertain quantities are normally distributed [13]–[16]. Having unbounded support, Gaussian disturbances make it impossible to satisfy state constraints uniformly; instead, chance constraints can be used. Dealing with chance constraints hinges on the normality assumption and requires that the involved random processes be independent [17], [18]. An approach for chance constraints that drops the normality assumption using polynomial chaos expansions and machine learning is presented in [19].

Scenario-based approaches seem to be more popular in MG control [7], [16], [20]–[24], mainly because scenario trees can be constructed from data [25]–[27] and the assumption of independence does not need to be imposed. In [21], a scenario-based approach combining an optimal operation scheduling with an MPC and assuming uncertain weather and load was proposed. Furthermore, [7] was extended in [22] to a two-stage stochastic MPC approach, which was formulated using scenario trees. In [23], a scenario-based optimal operation control strategy for droop-controlled MGs is presented, where a heuristic particle swarm optimization is used to minimize the expected objective value while accounting for power limitations of the transmission lines. A stochastic continuous-time rolling horizon control strategy that considers uncertain load can be found in [24]. However, this approach disregards the power flow over the transmission lines, possible power sharing among grid-forming units, and the possibility to limit the power provided by RES. There exist other scenario-based approaches [16] that account for power flow. However, [16] does not allow to limit infeed from RES. One approach that includes power flow, curtailable RES, and power sharing is the scenario-based stochastic MPC presented in [20].

Scenario-based MPC approaches that minimize the expectation of the cost assume that the scenario tree offers an adequate representation of the underlying probability distribution. The realization that this assumption does not always hold led to the emergence of risk-averse MPC [28], [29], which aims at safeguarding the controlled system from the effects of inexact knowledge of the underlying probability distribution.

### B. Risk-Based Approaches in Power Systems

Risk measures stem from the domains of operations’ research, stochastic finance, and actuarial science [30]. An example of a popular risk measure is the average value-at-risk (AVaR) [30]. When used in optimization problems, risk measures allow to mitigate the effects of inexact knowledge of the underlying probability distributions. They bridge the gap between conservative worst case approaches, which assume no knowledge about the underlying probability distribution, and stochastic approaches, which assume perfect knowledge about it. Therefore, risk-averse approaches are suitable for practical implementations, where probability distributions are not known exactly. In the case of operation management of MGs, it is likely that the predicted load and renewable infeed are uncertain and inaccurately estimated probability distribution. Such errors in the probability distribution can have a high impact on the controlled system. Therefore, it is important to design controllers that are robust with respect to forecast errors and errors in the determination of their probability distribution.

Although risk-averse problems enjoy favorable properties, their applicability has been limited by their complexity and computational cost of resulting multistage risk-averse optimal control problems. The reason is that their cost function is a composition of several nonsmooth mappings [30]. To date, there have only been slow numerical optimization methods (e.g., stochastic dual dynamic programming) limited to linear cost functionals [31], [32]. An alternative solution approach uses multiparametric piecewise quadratic programming [33], yet its applicability is limited to systems with a few states and small prediction horizons [34]. This has been daunting and risk-averse problems involving integer variables are considered overly computationally complex for real-time applications.

The study of risk-averse optimization problems is gaining popularity in power systems applications [35], such as unit commitment [36], scheduling [37], [38], and optimal power flow [39]–[41]. In [42], using AVaR, an approach for expansion and operation planning for a hydrothermal system is proposed. A multistage formulation for short-term trading with uncertain power from wind turbines and market prices is introduced in [43]. For grid-connected MGs, a comparison between a scenario-based risk-averse stochastic and a worst case optimization approach is presented in [35].

Despite their increasing popularity, most risk-averse approaches [36], [38], [42], [45] are based on simple formulations, which fail to capture how risk propagates in time. Proper multistage formulations lead to intricate optimization problems, where the cost function is expressed as a composition of nonsmooth mappings. This makes them less suitable for MPC [28], where fast computations are required. Therefore, in this paper, we use a reformulation that decomposes these nested mappings and allows to solve risk-averse MPC problems online.

### C. Contributions

In brief, the contributions of this paper are as follows: 1) we introduce a novel constrained hybrid dynamical model for islanded MGs; 2) we propose a multistage risk-averse MPC
problem for the optimal operation of an MG; 3) we reformulate the risk-averse optimal control problem in a computationally tractable way; and 4) we demonstrate the properties of the proposed operation control scheme in a simulation case study.

First, we present the model of an islanded MG with uncertain renewable generation and loads that allows for configurations with very high share of RES. This model, motivated by [10] and [20], considers a possible limitation of renewable infeed while limitations on transmission motived by [10] and [20], considers a possible limitation configurations with very high share of RES. This model, uncertain renewable generation and loads that allows for the risk-averse optimal control problem in a computationally problem for the optimal operation of an MG; 3) we reformulate the risk-averse optimal control problem in a computationally tractable way; and 4) we demonstrate the properties of the proposed operation control scheme in a simulation case study.

Second, we extend [10] and [20] to formulate a risk-averse MPC problem for islanded MGs. Unlike risk-neutral stochastic MPC [20], [44], where a large number of scenarios is needed for an accurate representation of the distributions, risk-averse MPC allows for fewer scenarios, as it mitigates the effect of uncertainty in the estimated probability distribution. This allows for robustness against bad forecast models of load and renewable infeed, time-varying probability distributions, or approximation errors in the scenario tree generation. Risk-averse formulations allow to interpolate between worst case [10] and stochastic [20] MPCs to specify the acceptable level of risk and provide resilience against high-effect low-probability events.

Third, motivated by [28], we use an epigraphical relaxation to reformulate the original risk-averse problem as a mixed-integer quadratically-constrained quadratic problem (MIQCQP). This way we decompose the original nested formulation and render the problem formulation suitable for real-time applications.

Fourth, in a comprehensive case study, we demonstrate the use of the proposed risk-averse MPC scheme for a simple MG. We juxtapose the operation of the MG using a stochastic, worst case, and a risk-averse formulation to show that the conservativeness of the controller can be tuned. Lastly, the robustness with respect to uncertainties in the probability distribution of load and RES is investigated by means of a sensitivity analysis.

D. Structure of This Paper

The remainder of this paper is structured along the lines of Fig. 1. In Section II, the model of an islanded MG is introduced. Then, scenario trees are derived from time-series-based forecasts in Section III. In Section IV, we quantify the operating costs of the MG. Subsequently, risk measures are discussed in Section V and a risk-averse MPC approach is derived in Section VI. Finally, in Section VII, the properties of the resulting MPC are illustrated in a numerical case study.

E. Notation

Real and natural numbers are denoted by \( \mathbb{R} \) and \( \mathbb{N} \), respectively. The set of nonnegative integers is denoted by \( \mathbb{N}_0 \). The set \( \{x | x \in \mathbb{N}_0 \wedge a \leq x \leq b\} \) is denoted by \( \mathbb{N}_{[a,b]} \). Furthermore, the set of nonnegative real numbers is \( \mathbb{R}_{\geq 0} \) and the set of positive real numbers is \( \mathbb{R}_{>0} \). The cardinality of a set \( V \) is denoted by \( |V| \). The transpose of a vector \( a \) is \( a^\top \). The vector \( [a_1, a_2, \ldots, a_N]^\top \) composed of elements \( a_i \) for all \( v_i \in V = \{v_1, v_2, \ldots, v_N\} \subset \mathbb{N} \) with \( v_i < v_j \) for \( i < j \), \( i \in \mathbb{N}_{[1,N]} \), \( j \in \mathbb{N}_{[1,N]} \) is denoted by \( [a_i]_{i \in V} \). A vector of dimension \( N \) whose elements are all equal to \( 1 \) is denoted by \( 1_N \). Let \( a = [a_1, a_2, \ldots, a_N]^\top \). Then, \( \text{diag}(a) \) denotes the diagonal matrix with entries \( a_i, i \in \mathbb{N}_{[1,N]} \).

When used with vectors, the relations \( \geq, \leq, <, > \) are understood element-wise. Function \( \max(a, b) \) returns the element-wise maximum of the vectors \( a \) and \( b \). However, if the function is used with only one vector input argument, i.e., \( \max(a) \), then it returns the largest element of the vector \( a \). The same holds for the minimum function \( \min(.) \). We denote by \( \min_{x \in \mathcal{X}} f(x) \) the minimum value of function \( f \) over \( \mathcal{X} \) and by \( \max_{x \in \mathcal{X}} f(x) \) the maximum value of \( f \) over \( \mathcal{X} \).

II. Microgrid Model

In this section, we derive a control-oriented mathematical model of an islanded MG. The model includes loads, conventional, renewable, and storage units, as well as transmission lines. The example of a basic MG that includes all these components is shown in Fig. 7. The MG model has the form

\[
\begin{align*}
    x(k) + Bq(k) - x(k+1) &= 0 \quad (1a) \\
    H_1 \cdot x(k+1) &\leq h_1 \quad (1b) \\
    H_2 \cdot [v(k)^\top q(k)^\top w(k)^\top]^\top &\leq h_2 \quad (1c) \\
    G \cdot [v(k)^\top q(k)^\top w(k)^\top]^\top &= g \quad (1d)
\end{align*}
\]

where \( k \in \mathbb{N}_0 \) is the discrete time instant. Here, \( x(k) \in \mathbb{R}^S \) with \( S \in \mathbb{N} \) is the state vector and \( q(k) \in \mathbb{R}^Q \) is a vector of \( Q \in \mathbb{N} \) auxiliary variables. The control inputs are collected in the vector \( v(k) = [u(k)^\top \delta k(k)^\top]^\top \), where \( u(k) \in \mathbb{R}^U \) is the vector of real-valued control inputs of all \( U \in \mathbb{N} \) units and \( \delta_k(k) \in \{0, 1\}^T \) is the vector of \( T \in \mathbb{N} \) Boolean inputs.
The uncertain external inputs of the model are collected in the vectors \( w(k) \in \mathbb{R}^W \), \( W \in \mathbb{N} \). In (1a), \( B \in \mathbb{R}^{S \times Q} \) and in (1b), \( H_1 \) and \( h_1 \) are of appropriate dimensions. Furthermore, in (1c), \( H_2 \) is a matrix and \( h_2 \) is a vector of appropriate dimensions that reflect inequality constraints. Likewise, in (1d), \( G \) is a matrix and \( g \) is a vector of appropriate dimensions that reflect equality constraints.

In what follows, we will derive a control-oriented MG model of the form (1). We start by posing some assumptions.

**Assumption 1 (Lower Control Layers):** The lower control layers, i.e., primary and secondary control, are designed such that the MG can run autonomously for several minutes, so providing power set points to the units on the same timescale is sufficient. These control layers ensure a desired power sharing [46], [47] among the grid-forming units.

**Assumption 2 (Conventional Units):** The start-up and shutdown times of the conventional units are small compared with the sampling time of MPC, i.e., switching actions are assumed to be instantaneous. Changes in power are instantaneous, i.e., no climb rates need to be considered.

**Assumption 3 (Storage Units):** The state of charge can be sufficiently and accurately estimated and is accessible to the operation control. The error introduced by neglecting self-discharge and conversion losses of storage units is small compared to the uncertainty introduced by renewable infeed and loads.

**Assumption 4 (Transmission Lines):** The resistance of the transmission lines between the units and loads of the MG as well as the reactive power flow are negligible. The voltage amplitudes in the grid are constant and the phase angle differences are small, so the dc power flow approximations [48] can be used. The error introduced hereby is small compared to the uncertainty introduced by renewable infeed and loads.

### A. Plant Model Interface

As summarized in Table I, the real-valued manipulated variables are the power set points of the units \( u(k) = [u_t(k)^\top \ u_s(k)^\top \ u_R(k)^\top]_T \in \mathbb{R}^u \), where \( u_t(k) \in \mathbb{R}^{T \geq 0} \) are the set points of the \( T \) conventional units, \( u_s(k) \in \mathbb{R}^S \) are the set points of the \( S \) storage units, and \( u_R(k) \in \mathbb{R}^{R \geq 0} \) are the set points of the \( R \) RES. Every conventional unit is associated with a Boolean input that indicates whether it is enabled or disabled. All Boolean inputs are collected in a vector \( \delta(k) \in \{0, 1\}^T \). Furthermore, the stored energies of the storage units are collected in the state vector \( x(k) \in \mathbb{R}^S \). The uncertain external inputs of the model are \( w(k) = [w_t(k)^\top \ w_s(k)^\top]_T \), where \( w_t(k) \in \mathbb{R}^{T \geq 0} \) represents the maximum available power of the renewable units under given weather conditions and \( w_s(k) \in \mathbb{R}^{D \geq 0} \) the load.

### B. Power of Units

In the islanded mode, equilibrium of production, consumption, and storage power must be ensured in the presence of uncertain load and renewable infeed. Therefore, the power of the units \( p(k) \in \mathbb{R}^U \) is not necessarily equal to the set points \( u(k) \). The vector of power values \( p(k) = [p_t(k)^\top \ p_s(k)^\top \ p_R(k)^\top]_T \) is composed of the power of conventional units, \( p_t(k) \in \mathbb{R}^T_{\geq 0} \), storage units, \( p_s(k) \in \mathbb{R}^S \), and RES, \( p_R(k) \in \mathbb{R}^R_{\geq 0} \).

1) **RES Units:** The power provided by the renewable units, \( p_t(k) \), and the corresponding set points, \( u_t(k) \), are limited by

\[
\begin{align*}
 p_t^{\text{min}} &\leq p_t(k) \leq p_t^{\text{max}} \quad (2a) \\
p_t^{\text{min}} &\leq u_t(k) \leq p_t^{\text{max}} \quad (2b)
\end{align*}
\]

with \( p_t^{\text{min}} \in \mathbb{R}^R_{\geq 0} \) and \( p_t^{\text{max}} \in \mathbb{R}^R_{\geq 0} \). Additionally, the power infeed \( w_t(i) \in \mathbb{R}^R_{\geq 0} \) of every renewable unit \( i \in \mathbb{N}_{[1,R]} \) can be limited by the power set point \( u_t(i) \in \mathbb{R}^R_{\geq 0} \). However, the power only follows the set point if the maximum possible infeed under current weather conditions \( w_{t,i}(k) \in \mathbb{R}^T_{\geq 0} \) is greater than or equal to \( u_{t,i}(k) \).

Using the element-wise min operator, this can be described by

\[
p_t(k) = \min(u_t(k), w_t(k)).
\]

For the formulation of the optimization problem, it is beneficial to transform (3) into a set of linear inequalities involving integer variables. This is done by introducing the free variable \( \delta_t(k) \in \{0, 1\}^R \). With the constants \( m_t \in \mathbb{R} \), \( m_t < \min(p_t^{\text{min}}) \), and \( M_t \in \mathbb{R}^R_{\geq 0} \), \( M_t > \max(p_t^{\text{max}}) \) which are calculated off line, we then exactly reformulate (3) as [49]

\[
\begin{align*}
p_t(k) &\leq u_t(k) \quad (4a) \\
p_t(k) &\geq u_t(k) + (\text{diag}(w_t(k)) - M_t I_R)\delta_t(k) \quad (4b) \\
p_t(k) &\leq w_t(k) \quad (4c) \\
p_t(k) &\geq w_t(k) - (\text{diag}(w_t(k)) - m_t I_R)(1 - \delta_t(k)). \quad (4d)
\end{align*}
\]

2) **Conventional Units:** The power provided by conventional unit \( i \in \mathbb{N}_{[1,T]} \) is limited by \( p_t^{\text{min}} \in \mathbb{R}^T_{\geq 0} \) and \( p_t^{\text{max}} \in \mathbb{R}^T_{\geq 0} \) if it is enabled, i.e., if \( \delta_t(i) = 1 \). If the unit is disabled, i.e., \( \delta_t(i) = 0 \), then naturally \( p_t(i) = 0 \). In vector notation with \( p_t^\text{min} \in \mathbb{R}^T_{\geq 0} \) and \( p_t^\text{max} \in \mathbb{R}^T_{\geq 0} \), this can be expressed by

\[
\text{diag}(p_t^{\text{min}})\delta_t(k) \leq p_t(k) \leq \text{diag}(p_t^{\text{max}})\delta_t(k). \quad (5a)
\]
The same holds for the power set points, that is
\[ \text{diag}(p_{i \text{min}}) \delta_i(k) \leq u_i(k) \leq \text{diag}(p_{i \text{max}}) \delta_i(k). \]  

(5b)

3) Storage Units: As the storage units are assumed to be always enabled, all their set points and power values are limited by \( p_{s \text{min}} \in \mathbb{R}^S_{\leq 0} \) and \( p_{s \text{max}} \in \mathbb{R}^S_{\geq 0}, \) that is
\[ p_{s \text{min}} \leq p_s(k) \leq p_{s \text{max}} \]  

(6a)

\[ p_{s \text{min}} \leq u_s(k) \leq p_{s \text{max}}. \]  

(6b)

C. Power Sharing of Grid-Forming Units

Due to variations of load and renewable infeed, the power of all units does not necessarily match the power set points that are prescribed to the system. The grid-forming units, i.e., all storage and conventional units, are assumed to be controlled by the lower control layers such that they share the changes in load and renewable infeed in a desired proportional manner. This so-called proportional power sharing [46], [47] depends on the design parameter \( \chi \in \mathbb{R}^{-} \) for all grid-forming units. A typical choice of \( \chi \) is proportional to the nominal power of the corresponding units.

Power sharing can be formalized as follows. Two units \( i \in [N, 1 + T + S] \) and \( j \in [N, 1 + T + S], i \neq j \) with \( \chi = \pi \chi \in \mathbb{R}^{-} \) and \( \chi_j \in \mathbb{R}^{-} \) are said to share their power proportionally, if
\[ \frac{p_i(k) - u_i(k)}{\chi_i} = \frac{p_j(k) - u_j(k)}{\chi_j} \]  

(7)

holds. Using the auxiliary free variable \( \rho(k) \in \mathbb{R} \) and including that only enabled units, i.e., units \( i \) with \( \delta_i = 1, \) can participate in power sharing, we can rewrite (7) for all grid-forming units with \( K_1 = \text{diag}((1/\chi_1) \cdots (1/\chi_T)) \) and \( K_S = \text{diag}((1/(\chi_{T+1}) \cdots (1/(\chi_{T+S}))) \) as
\[ K_i(p_i(k) - u_i(k)) = \rho(k) \delta_i(k) \]  

(8a)

\[ K_s(p_s(k) - u_s(k)) = \rho(k) 1_S. \]  

(8b)

To proceed with what follows, we need to transform (8a) into a set of linear inequalities with integer variables. This can be done using a similar strategy as described in [49]. First, we choose \( M_i \in \mathbb{R} \), which can be calculated off line. The value of \( M_i \) should be greater than the biggest possible value of \( \rho(k). \) Hence, with the biggest possible value for the storage units, \( p_{s \text{max}} = \max(K_S(p_{s \text{max}} - p_{s \text{min}})), \) and for the conventional units, \( p_{t \text{max}} = \max(K_t(p_{t \text{max}} - p_{t \text{min}})), \) \( M_i \) has to be chosen such that \( \max(p_{s \text{max}} - p_{s \text{min}}) < M_i. \) Then, with \( m_i = -M_i, \) we can exactly reformulate (8a) as
\[ K_i(p_i(k) - u_i(k)) \leq M_i \delta_i(k) \]  

(9a)

\[ K_i(p_i(k) - u_i(k)) \geq m_i \delta_i(k) \]  

(9b)

\[ K_i(p_i(k) - u_i(k)) \leq 1_T \rho(k) - m_i (1_T - \delta_i(k)) \]  

(9c)

\[ K_i(p_i(k) - u_i(k)) \geq 1_T \rho(k) - M_i (1_T - \delta_i(k)). \]  

(9d)

D. Dynamics of Storage Units

The dynamics of all storage units are assumed as
\[ x(k + 1) = x(k) - T_s p_s(k) \]  

(10a)

where \( T_s \in \mathbb{R}^{-} \) is the sampling time. The stored energy is represented by \( x(k) \) with initial state \( x(0) = x_0. \) To cover the limited storage capacity, \( x(k + 1) \) is bounded by
\[ x_{\text{min}} \leq x(k + 1) \leq x_{\text{max}} \]  

(10b)

with \( x_{\text{min}} = 0_S \) and \( x_{\text{max}} = x_{\text{max}}. \)

Remark 5: In the simulations in Section VII, we use a more detailed plant model that is different from (10a). This storage model is motivated by [7] and includes self-discharge as well as charging and discharging efficiencies. It reads
\[ x(k + 1) = \begin{cases} x(k) - T_s 1_S \eta^\text{ch} p_s(k) - x_{\text{sd}}, & \text{if } p_s(k) \leq 0 \\ x(k) - T_s (\eta^\text{d})^{-1} p_s(k) - x_{\text{sd}}, & \text{if } p_s(k) > 0 \end{cases} \]  

(11)

Here, \( \eta^\text{ch} \in (0, 1)^{S \times S} \) is the diagonal matrix of charging efficiencies of the units and \( \eta^\text{d} \in (0, 1)^{S \times S} \) is the diagonal matrix of discharging efficiencies, both with nonzero diagonal elements. Furthermore, \( x_{\text{sd}} \in \mathbb{R}^{S \times 0} \) models self-discharge.

The simplified storage dynamics of the control-oriented model (10a) can be derived from (11) by assuming that \( \eta^\text{ch} = \eta^\text{d} = \text{diag}(1_S) \) and that \( x_{\text{sd}} = 0_S. \) Note that (10a) is used in an MPC context, where the state is sampled at every time instant and used as initial value to predict future states. Such a strategy allows to use of less accurate models due to its inherent robustness [50]. Furthermore, the error introduced by uncertain renewable infeed and load is assumed to be much larger than the one introduced by (10a) (see Assumption 2.3).

Therefore, the simplification is of minor importance.

E. Transmission Network

The power transmitted over the lines can be derived using dc power flow approximations for ac grids [10], [48]. Thus, the power flowing over the \( E \) transmission lines, \( p_e(k) = [p_{e,1}(k) \cdots p_{e,E}(k)]^\top, \) can be derived from the power of the units and the load using the linear relation
\[ p_e(k) = F \cdot [p(k)^\top \ u_w(k)^\top]^\top \]  

(12a)

where \( F \in \mathbb{R}^{E \times (U + D)} \) is a matrix that links the power flowing over the lines with the power provided or consumed by the units and loads. More information on the derivation of \( F \) can be found in [10] and [51]. Due to the limited transmission capability of the lines, \( p_e(k) \) is desired to be bounded by
\[ p_{e \text{min}} \leq p_e(k) \leq p_{e \text{max}} \]  

(12b)

with \( p_{e \text{min}} \in \mathbb{R}^{E \times 0} \) and \( p_{e \text{max}} \in \mathbb{R}^{E \times 0}. \) Additionally, the generated power must equal consumed power at all times, i.e.,
\[ 1_T^\top p_i(k) + 1_S^\top p_s(k) + 1_R^\top p_t(k) = 1_D^\top u_w(k). \]  

(12c)

Remark 6: There are small MGs in which all units are directly connected to a single bus, e.g., in [7] and [22]. Such MGs can be modeled in two ways with (12): 1) discard constraints (12a) and (12b) and only keep (12c) and 2) set \( F = [1_U - 1_D]. \) Due to (12c), in this case, \( p_e(k) = 0 \) holds for all \( k \in \mathbb{N}_0 \) and the limits can be chosen as \( p_{e \text{min}} = p_{e \text{max}} = 0. \)

Remark 7: For the plant simulation model in Section VII, we use the nonlinear power flow equations [47], [52]. Thus,
the power provided or consumed by unit or load \( i \in \mathbb{N}_{[1, J]} \), where \( J = U + D \) is the total number of units and loads, is
\[
p_{e,i}(k) = \hat{b}_i \sum_{j=1}^{J} \hat{b}_j g_{ij} - \hat{b}_j (g_{ij} \cos(\theta_{ij}(k)) + b_{ij} \sin(\theta_{ij}(k))).
\]
(13)

Here, \( \hat{b}_i \in \mathbb{R}_{>0} \) is the voltage amplitude at node \( i \) and \( \theta_{ij}(k) = \theta_i(k) - \theta_j(k) \) is the difference between the phase angles \( \theta_i(k) \in \mathbb{R} \) at node \( i \) and \( \theta_j(k) \in \mathbb{R} \) at node \( j \in \mathbb{N}_{[1, J]} \). Furthermore, \( g_{ij} \in \mathbb{R}_{>0} \) is the conductance and \( b_{ij} \in \mathbb{R} \) is the susceptance of the line connecting nodes \( i \) and \( j \).

Note that (12a) can be derived from (13) using Assumption 2.4, i.e., assuming inductive lines with \( g_{ij} = 0 \), constant voltage amplitudes \( \hat{b}_i \), and small angle differences \( \theta_{ij}(k) \) such that \( \sin(\theta_{ij}(k)) \approx \theta_{ij}(k) \) can be used for all \( i, j \in \mathbb{N}_{[1, J]} \). With these assumptions and with \( \hat{b}_ij = -\hat{b}_i \hat{b}_j b_{ij} \), (13) becomes
\[
p_{e,i}(k) = \sum_{j=1}^{J} \hat{b}_j \theta_{ij}(k).
\]
(14)

This equation can now be used to derive matrix \( F \) in (12a) [12]. Although more accurate convex power flow models exist [53], we assume that the error introduced by uncertain renewable infeed and load is much larger than the one introduced by (12a) (see Assumption 2.4).

\section{F: Overall Model}

Having discussed the different components of the islanded MG, we can now derive a control-oriented model of the form (1) based on (2), (4)–(6), and (8b)–(12). Here, the auxiliary vector is \( q(k) = [p(k) \top \delta(k) \top \rho(k)] \top \). Moreover, \( B = [0_{S \times T} - T_s L_s 0_{S \times 2R+1}] \), \( H_1 = \text{diag}([1_y - 1_z]) \), and \( h_1 = [x^{\text{max}} \top - x^{\text{min}} \top]^\top \). Furthermore, \( H_2 \) and \( h_2 \) in (1c) are formed such that they reflect (2), (4)–(6), (9), and (12b). Additionally, \( G \) and \( g \) in (1d) are formed such that they reflect (8b), (12a), and (12c).

\section{III. Uncertainty Model}

This section focuses on the representation of uncertain load and renewable infeed. First, the generation of a collection of forecast scenarios is discussed. Then, scenario trees are illustrated and the model of an MG with uncertain load and renewable generation is derived.

\subsection{A. Representation of Uncertainty by Collections of Scenarios}

To obtain a representative probability distribution of load and renewable infeed for the controller, a sampling-based Monte Carlo forecast was chosen. Here, random samples that follow the error distribution obtained from the training of the forecast model are drawn and applied to the forecast to generate a collection of independent scenarios, where every scenario has the same probability. Thus, for a high number of independent forecast scenarios, the probability distribution of the forecast is approximated. To generate scenarios of load and available renewable power, the seasonal ARIMA models from [20] were used (see Fig. 2). For more information on time-series-based forecasting, the reader is referred to [54].

To achieve a sufficiently accurate approximation of the forecast probability distribution, a high number of independent forecast scenarios are desired. This leads to an undesired high computational complexity in finding a suitable control action as a high number of scenarios often lead to a high number of decision variables. To satisfy both needs sufficiently, we generate scenario trees, which serve as a more compact representation of the probability distribution.

\subsection{B. From Data to Scenario Trees}

Scenario trees can be constructed from collections of forecast scenarios. They can be obtained using methodologies such as [55] or scenario reduction [26], [27]. There exist several other scenario generation algorithms, e.g., clustering-based [56], [57] and simulation and optimization-based approaches [58], [59]. An example of such a collection of independent forecast scenarios and the corresponding scenario tree for a forecast of load and available wind power is shown in Fig. 2 (right). This tree was generated using fast forward selection as described in [60, Algorithm 5], which is a modification of [26, Algorithm 2.4].

\subsection{C. Representation of Uncertainty Using Scenario Trees}

A scenario tree is a representation of the uncertain evolution of a discrete-time finite-valued random process, as shown in Fig. 3. A tree is a collection of \( \mu \in \mathbb{N} \) nodes partitioned into stages \( j \in \mathbb{N}_{[0, \mu]} \) and indexed with a unique identifier \( i \in \mathbb{N}_{[0, \mu-1]} \). Each node is associated with a possible value of the state of the process at a future time instant starting from an initial node \( i = 0 \) at stage \( j = 0 \), which is called the root node of the tree. The set of nodes at stage \( j \) is denoted by \( \text{nodes}(j) \subseteq \mathbb{N}_{[0, \mu-1]} \). Conversely, the stage in which a node \( i \) resides is denoted by \( \text{stage}(i) \in \mathbb{N}_{[0, \mu]} \). The nodes at stage \( j = N \) are called leaf nodes. All non-leaf nodes \( i \)
Consequently, different values of the auxiliary vector will occur. These sequences are nodes at stage $j + 1$. Likewise, every node $i \neq 0$ is reachable from a single ancestor node, which resides in the previous stage and is denoted by $\text{anc}(i) \subseteq \text{nodos}(j + 1)$. A scenario is a sequence of nodes $(s_0, \ldots, s_N)$ such that $s_N \in \text{nodos}(N)$ and $\text{anc}(s_\ell) = s_{\ell-1}$, $\ell \in \mathbb{N}_{[1, N]}$. Scenarios are uniquely identified by leaf nodes. The probability of visiting node $i \in \mathbb{N}_{[0, N-1]}$ is denoted by $\pi^i > 0$. That said, at stage $j$, the set $\text{nodos}(j)$ is a probability space with $\sum_{i \in \text{nodos}(j)} \pi^i = 1$.

For the tree shown in Fig. 3, the relation of the different variables at $j = 0$ and $j = 1$ is shown in Fig. 4. As shown here, we make a decision $v(0)$ at stage $j = 0$ without knowing which disturbance $w(1)$ or $w(2)$ will occur during the time between $j = 0$ and $j = 1$. Depending on the disturbance $w$, different values of the auxiliary vector $q$ will occur. These can be calculated using the function $f_q(\cdot, \cdot)$ derived from (1). Thus, the choice of $v(0)$ accounts for $q(1) = f_q(v(0), w(1))$ and $q(2) = f_q(v(0), w(2))$ without knowing which occurs. Similarly, following (1a), the state $x$ at time instant $j = 1$ is a function $f_x(\cdot, \cdot)$ of the state at time instant $j = 0$ and the auxiliary vector that is present between $j = 0$ and $j = 1$. Consequently, different values $q(1)$ and $q(2)$ lead to different states

$$
\begin{align*}
  x(1) &= f_x(x(0), q(1)) = f_x(x(0), f_q(v(0), w(1))) \\
  x(2) &= f_x(x(0), q(2)) = f_x(x(0), f_q(v(0), w(2))).
\end{align*}
$$

In summary, given an initial measured system state $x(0)$ at stage $j = 0$ and a forecast in the form of $w(1)$ or $w(2)$, we make a decision $v(0)$ using this information. Similarly, at every stage $j \in \mathbb{N}_{[0, N-1]}$, we make decisions $v(j)$, $i \in \text{nodos}(j)$, using the information that is available up to that stage and using the forecast values $w(i)$ for $i \in \text{child}(i)$. In other words, $v$ is decided using causal control laws. This is indicated in Fig. 3 by the positioning of $v(j)$ at the nodes of the tree instead of at its edges. Thus, across the nodes of the scenario trees, the control-oriented model (1) for all nodes $i \in \mathbb{N}_{[1, N-1]}$ with $i = \text{anc}(i)$ becomes

$$
\begin{align*}
  x(i) + B q(i) - x(i) &= 0 & (15a) \\
  H_1 \cdot x(i) &\leq h_1 & (15b) \\
  H_2 \cdot [y(i) \cdot y(i) \cdot w(i)] &\leq h_2 & (15c) \\
  G \cdot [y(i) \cdot y(i) \cdot w(i)] &\geq g. & (15d)
\end{align*}
$$

IV. OPERATING COSTS

In this section, we derive an operating cost function for an MG, which reflects the main objectives: 1) economic operation; 2) a low number of switching actions; 3) high use of RES; and 4) desired state of storage units. We use cost functions that are motivated by [20]. Our presentation will hinge on the scenario tree structure introduced in Section III-C, i.e., objectives will be defined at the nodes of a scenario tree.

The objective at node $i_+ \in \mathbb{N}_{[1, \mu]}$ with $i = \text{anc}(i_+)$ and $i_- = \text{anc}(i)$ is composed of $\ell \circ (v(i), q(i)) = \in \mathbb{R}_{\geq 0}$ that reflects items 1–3 and $\ell_s(x(i)) \in \mathbb{R}_{\geq 0}$ that reflects item 4. A discount factor $\gamma \in (0, 1)$ is used to emphasize decisions in the near future. Thus, the cost associated with node $i_+$

$$
\ell(x(i_+), v(i_+), v(i_-), q(i_+)) = \gamma \ell_s(x(i)) + \ell(x(i_+), v(i_+), q(i_+)).
$$

Remark 8: Note that the cost associated with node $i_+ = \ell_s(x(i_+), v(i_+), q(i_+))$, also depends on nodes $i = \text{anc}(i_+)$ and $i_- = \text{anc}(i)$. The reason for this is that $q(i_+)$ is a function of the input $v(i)$ (see Section III-C). Therefore, it is required to use $\ell_s(x(i_+))$ and $\ell_v(i)$ with $i = \text{anc}(i_+)$ in the same cost function. As the cost that is caused by $v(i)$ partly depends on the input at the past time instant, e.g., in case of switching penalties, it is further required to include $v(i_-)$.

The economically motivated cost includes: 1) operating costs of conventional units, $\ell_{t}^v(v(i), q(i)) \in \mathbb{R}_{\geq 0}$; 2) costs for switching conventional units on or off, $\ell_{t}^w(v(i), u(i)) \in \mathbb{R}_{\geq 0}$; and 3) costs incurred by low utilization of renewable sources, $\ell_t(q(i)) \in \mathbb{R}_{\geq 0}$, that is

$$
\ell \circ (v(i), q(i)) = \ell_{t}^v(v(i), q(i_+)) + \ell_{t}^w(v(i), u(i)) + \ell_t(q(i_+)).
$$

More precisely, following [61], the operating cost of the conventional units is modeled as:

$$
\ell_{t}^v(v(i), q(i_+)) = c_1^t \delta(i_+) + c_1^t \delta(t(i_+)) + \| \text{diag}(c_2^t) \delta(t(i_+)) \|_2^2
$$

(18a)

with weights $c_1 \in \mathbb{R}_{> 0}$, $c_1^t \in \mathbb{R}_{> 0}$, and $c_2^t \in \mathbb{R}_{> 0}$ and using the square of the Euclidean norm $\| \cdot \|_2^2$.

Costs for switching the conventional units on or off from node $i_- = \text{anc}(i)$ to node $i$ are modeled by

$$
\ell_{t}^w(v(i), u(i_-)) = \| \text{diag}(c_1^w) \delta(i_-) - \delta(i) \|_2^2
$$

(18b)
with weight $c^w_i \in \mathbb{R}^T_{\geq 0}$. For the root node, $s_0^{(0)}$ denotes the initial switch state of the conventional units, $\delta_{t,k-1}$.

It is desired to maximize renewable infed. This can be included in the stage cost as a penalty if the renewable infed is less than the nominal value $p_t^{\text{max}}$, i.e., with $c_t \in \mathbb{R}^R_{\geq 0}$

$$\ell_t(q^{(i_i)}) = \| \text{diag}(c_t)(p_t^{\text{max}} - p_t^{(i_i)}) \|_2^2. \quad (18c)$$

Very high or very low values of $x(k)$ can increase the aging of batteries [62]. To reduce the occurrence of such values, we introduce the interval of desired values of $x(k)$, $[x_{\min}, x_{\max}] \subseteq [x_{\min}, x_{\max}]$. To enforce $x(k) \in [x_{\min}, x_{\max}]$, we define $\ell_s(x^{(i_i)})$ with $c_\pi \in \mathbb{R}_{\geq 0}^R$ as

$$\ell_s(x^{(i_i)}) = c_\pi^T (\max(x_{\min} - x^{(i_i)}, 0_S) - \min(x_{\max} - x^{(i_i)}, 0_S)). \quad (19)$$

For every node $i_+ \in \mathbb{N}_{[1,\mu-1]}$ with $i_+ \in \text{child}(i)$ as well as $i_- = \text{anc}(i)$, we define the cost variable

$$Z_{i_+} = \ell_t(x^{(i_+)}) = \ell(x^{(i_+)}, v^{(i_+)}, v^{(i_-)}, q^{(i_+)}). \quad (20a)$$

Thus, for stage $j \in \mathbb{N}_{[1,N]}$, the vector

$$Z_j = [Z_{i_+}]_{i_+ \in \text{nodes}(j)} \quad (20b)$$

is associated with a random variable on the probability space \(\Omega\). Note that $Z_j \in \mathbb{R}^{\text{nodes}(j)}$ is a function of states $\chi^{(i_+)}$, inputs $v^{(i_+)}$, and auxiliary variables $q^{(i_+)}$ for all $i_+ \in \text{nodes}(j)$, $i_+ = \text{anc}(i)$ and $i_- = \text{anc}(i)$. Using (20b), we can describe the multistage cost by the sequence \((Z_1, \ldots, Z_N)\).

V. MEASURING RISK

In this section, we introduce the notion of risk measures and provide a few examples thereof. Furthermore, we will discuss one specific risk measure: the AVaR.

A. Introduction to Risk Measures

Let $\Omega = \{\omega_1, \ldots, \omega_K\}$ be a sample space, whose elements $\omega_i$ have probabilities $\pi_i > 0$ for $i \in \mathbb{N}_{[1,K]}$. The probabilities can be collected in a vector $\pi = [\pi_1 \cdots \pi_K]^T$. This vector is an element of the probability simplex, i.e., the set $\mathbb{D} = \{\pi \in \mathbb{R}^K \mid \pi_i \geq 0, \sum_{i=1}^K \pi_i = 1\}$. A random variable on $\Omega$ is a function $Z : \Omega \to \mathbb{R}$ with $Z(\omega_0) = Z_1$. All values of $Z$ can be collected in a vector $Z = [Z_1 \cdots Z_K]^T \in \mathbb{R}^K$. Note that in our case, these values are given by (20) and represent the operation cost at the nodes of the scenario tree.

A risk measure on $\Omega$ is a mapping $\rho : \mathbb{R}^K \to \mathbb{R}$ that, roughly speaking, quantifies the significance of extreme events. A well-known, yet trivial, risk measure is the expectation operator $\mathbb{E}_\pi(Z) = \sum_{i=1}^K \pi_i Z_i$, which is often referred to as a risk-neutral measure, as it carries no deviation information. Another example of a risk measure is the maximum operator $\max(Z) = \max[Z_i \mid i = 1, \ldots, K]$, which quantifies the worst case value, or realization, of $Z$. It can be written as

$$\max(Z) = \max_{\pi \in \mathbb{D}} \mathbb{E}_\pi(Z) \quad (21)$$

where the maximum is taken with respect to all probability vectors $\pi' \in \mathbb{D}$. Therefore, it can be interpreted as the worst case expectation over all possible probability distributions. Following the notation in (21), the expectation operator is:

$$\mathbb{E}_\pi(Z) = \max_{\pi' \in \mathbb{D}} \mathbb{E}_{\pi'}(Z). \quad (22)$$

In this paper, we focus on coherent risk measures, as they quantify risk in a natural and intuitive way. Also, they allow for a computationally tractable reformulation of risk-averse problems, which renders them suitable for MPC applications.

It is shown in [30, Thm. 6.5] that all coherent risk measures can be written in a form reminiscent of (21) and (22) as

$$\rho(Z) = \max_{\pi' \in \mathbb{A}_\alpha} \mathbb{E}_{\pi'}(Z) \quad (23)$$

where $\mathbb{A} \subseteq \mathbb{D}$ is a closed convex set that contains $\pi$. Every mapping of the form (23), where the so-called ambiguity set $\mathbb{A}$ of $\rho$ is a closed convex set which contains $\pi$, is coherent. One interpretation of (23) is that we take the worst case expectation of $Z$ with respect to $\pi' \in \mathbb{A}$, that is, with respect to an inexactly known distribution [63]. The expectation and maximum operators are two extreme cases of coherent risk measures. The ambiguity set of $\max(Z)$ is the largest possible set, i.e., $\mathbb{A} = \mathbb{D}$. The ambiguity set of $\mathbb{E}(Z)$ is the smallest possible set, i.e., $\mathbb{A} = \{\pi\}$. Other risk measures can be constructed by taking ambiguity sets of intermediate size to cope with uncertain knowledge of a probability distribution.

Risk measures, whose ambiguity set is a polytope, are called polytopic. Given the extreme points of the ambiguity set, its vertices $\pi_1, \ldots, \pi_L$, they assume the convenient representation

$$\rho(Z) = \max_{l \in \mathbb{N}_{[1,L]}} \mathbb{E}_{\pi_l}(Z). \quad (24)$$

B. Average Value-at-Risk

A commonly used risk measure is the average value-at-risk, which is given in the form of (23) as

$$\rho(Z) = \text{AV@R}_{\alpha}(Z) = \max_{\pi' \in \mathbb{A}_\alpha} \mathbb{E}_{\pi'}(Z) \quad (25a)$$

with the ambiguity set

$$\mathbb{A}_\alpha = \left\{ \pi' \in \mathbb{D} \mid \pi' \leq \frac{1}{\alpha} \pi \right\}, \quad \text{if } \alpha \in (0, 1]$$

$$\mathbb{D}, \quad \text{if } \alpha = 0 \quad (25b)$$

for $\alpha \in \mathbb{R}_{(0,1]}$. Clearly, AVaR is a polytopic risk measure since $\mathbb{A}_\alpha$ is a polytope. As shown in Fig. 5, $\mathbb{A}_\alpha$ can be modified by varying $\alpha$. This includes the extreme cases $\alpha = 1$, where $\mathbb{A}_1 = \{\pi\}$ and $\alpha = 0$, where $\mathbb{A}_0 = \mathbb{D}$. Using convex duality arguments and the additional free variable $t \in \mathbb{R}$, (25) can be transformed into [30, Ex. 6.19]

$$\text{AV@R}_{\alpha}(Z) = \min \left( t + \mathbb{E}_\pi \left( \max \left( \frac{Z - t 1_{K}}{\alpha}, 0_K \right) \right) \right), \quad \text{for } \alpha \in (0, 1]$$

$$\max(Z), \quad \text{for } \alpha = 0. \quad (26)$$

\footnote{Let $\bar{Z}$ and $\bar{Z}'$ be two random variables on $\Omega$ and $Z$ and $Z'$ be the corresponding vectors. Then, $\rho : \mathbb{R}^K \to \mathbb{R}$ is a coherent risk measure (see [30, Def. 6.4]) if it is: 1) convex, i.e., $\rho(\lambda Z + (1 - \lambda) Z') \leq \rho(Z) + (1 - \lambda)\rho(Z')$ for all $\lambda \in [0, 1]$; 2) monotone, i.e., $\rho(Z) \leq \rho(Z')$ whenever $Z \leq Z'$; 3) translation equi-variant, i.e., $\rho(c_1 K + Z) = \rho(Z)$ for all $c \in \mathbb{R}$; and 4) positive homogeneous, i.e., $\rho(\alpha Z) = \alpha \rho(Z)$ for all $\alpha \in \mathbb{R}_{\geq 0}$.}
We will now give an equivalent representation of the AVaR which will be useful in Section VI-C as it will facilitate the solution of risk-averse optimal control problems.

**Proposition 9:** The average value-at-risk at level \( \alpha \in [0, 1] \) is given by

\[
\text{AV}\text{-}@R_{\alpha}(Z) = \min_{\xi \geq 0} \left( t + E_\pi(\xi) \right)
\]

with the second equation being by the virtue of (28).

\[
\text{Proof: } \text{Let } \alpha \in (0, 1]. \text{ Using the epigraphical relaxation (see [64, Sec. 3.1.7 & 4.1]) of max}(\cdot, 0) \text{ we have that}
\]

\[
\max(y, 0_K) = \min_{\xi \geq 0} \xi
\]

for all \( y \in \mathbb{R}^K \), where \( \xi \in \mathbb{R}^K \) is a slack variable. Therefore

\[
\text{AV}\text{-}@R_{\alpha}(Z) = \min_{\xi \geq 0} \left( t + E_\pi \left( \max \left( \frac{Z - l_1 K}{\alpha}, 0_K \right) \right) \right)
\]

\[
= \min_{\xi \geq 0} \left( t + E_\pi \left( \min_{\xi \geq \frac{Z - l_1 K}{\alpha}} \xi \right) \right)
\]

\[
= \min_{\xi \geq 0} \left( t + E_\pi \left( \min_{\alpha \xi \geq Z - l_1 K} \xi \right) \right)
\]

The right-hand side of (27) is well defined for \( \alpha = 0 \) that is

\[
\text{AV}\text{-}@R_0(Z) = \min_{\xi \geq 0} \left( t + E_\pi \left( \xi \right) \right)
\]

\[
= \min_{t \xi \geq Z} \xi = \min_{t \xi \geq Z} t = \max(Z).
\]

Therefore, (27) holds for all \( \alpha \in [0, 1] \).

A conditional risk mapping on a scenario tree is a generalization of the notion of conditional expectation, which is the expectation of a random cost \( Z_{j+1} \) at stage \( j+1 \); given all information, we can surmise up to stage \( j \). Roughly speaking, a conditional risk mapping at a non-leaf node \( i \) of the tree returns the risk of the cost of the children of \( i \). Conditional risk mappings can be constructed as follows.

For every stage \( j \in \mathbb{N}_{0, N-1} \), the set \( \text{nodes}(j) \) is a probability space whose elements \( i \in \text{nodes}(j) \) have probability \( \pi(i) \). Naturally, we can define real-valued random variables with corresponding vectors \( Z_j \in \mathbb{R}^{\text{nodes}(j)} \) on that space. Likewise, the set \( \text{nodes}(j+1) \) is also a probability space. A conditional risk mapping at stage \( j \) is a mapping

\[
\rho_j : \mathbb{R}^{\text{nodes}(j+1)} \rightarrow \mathbb{R}^{\text{nodes}(j)}
\]

which is constructed as we explain hereafter.

For all \( i \in \text{nodes}(j) \), the sets \( \text{child}(i) \subseteq \text{nodes}(j+1) \) are disjoint and define a partition over \( \text{nodes}(j+1) \), i.e., \( \text{nodes}(j+1) = \bigcup_{i \in \text{nodes}(j)} \text{child}(i) \). Given that node \( i \) is visited, \( i \in \text{child}(i) \) occurs with probability \( \pi(i) / \pi(i) \). This makes \( \text{child}(i) \) into a probability space whereon we can construct random vectors with vectors \( Z[i] = Z[i]_{i \in \text{child}(i)} \). In particular, \( Z_{j+1} \) on the probability space \( \text{nodes}(j+1) \) is decomposed into vectors \( Z[i] \) on \( \text{child}(i) \), \( i \in \text{nodes}(j) \).

Using a coherent risk measure \( \rho(i) : \mathbb{R}^{\text{child}(i)} \rightarrow \mathbb{R} \), we can compute a risk \( \rho(i)(Z[i]) \) for every vector \( Z[i] \). Thus, we define the conditional risk mapping \( \rho_j \) at stage \( j \) as

\[
\rho_j(Z_{j+1}) = [\rho(i)(Z[i])]_{i \in \text{nodes}(j)}.
\]

In words, \( \rho_j \) maps the probability distribution at stage \( j+1 \) into a vector whose \( i \)th element denotes the risk that will incur if one is at node \( i \in \text{nodes}(j) \). For a simple scenario tree, this is shown in Fig. 6.

**Remark 10:** For the case where \( \rho(i)(Z[i]) \) is \( \text{AV}\text{-}@R_0(Z[i]) \), according to Proposition 5.1, the risk of \( Z[i] \) is

\[
\rho(i)(Z[i]) = \min_{\xi \geq 0_{\text{child}(i)}} (t(i) + E_{Z[i]}(\xi)).
\]
with \( t^{(i)} \in \mathbb{R} \) and \( \xi^{[i]} = [\xi^{(i)}]_{1 \leq i \leq \text{child}(i)}, \xi^{(i)} \in \mathbb{R} \) for \( i \in \mathbb{N}_{[0, \mu - 1]} \setminus \text{nodes}(N) \). As we consider the probability space \( \text{child}(i) \), we are interested in the probability of visiting \( i_+ \in \text{child}(i) \) given that we are at node \( i \). Therefore, the probabilities are \( \pi^{[i]} = ([\pi^{(i)}]_{l_i \in \text{child}(i)}) \) and (31) is equivalent to

\[
\rho^{(i)}(Z^{[i]}) = \min_{\xi^{[i]} \geq 0, \text{child}(i)} \left( t^{(i)} + \sum_{i_+ \in \text{child}(i)} \pi^{(i)} \xi^{(i)} \right). \tag{32}
\]

Having discussed conditional risk mappings on scenario trees, we can now use them to construct a multistage risk measure based on the vector \( Z = [Z^1_1 \cdots Z^N_1]^T \) that is associated with the multistage random variable.

### B. Risk-Averse Optimal Control

Let \( Z_j \in \mathbb{R}^{\text{nodes}(j)} \) be the cost in (20). For the sequence \((Z_1, \ldots, Z_N)\) and given a sequence of conditional risk mappings \( \rho_j \) of the form (30), the nested multistage risk measure \( \varrho_N : \mathbb{R}^{\text{nodes}(1)} \times \cdots \times \mathbb{R}^{\text{nodes}(N)} \rightarrow \mathbb{R} \) is [28]–[30]

\[
\varrho_N(Z_1, \ldots, Z_N) = \rho_0(Z_1 + \rho_1(Z_2 + \cdots + \rho_{N-1}(Z_N))) \ldots. \tag{33}
\]

Nested multistage risk measures possess favorable properties, which render them suitable for optimal control formulations. The most important properties are as follows.

1) They are suitable for multistage formulations as they measure how risk propagates over time.
2) They are coherent risk measures over the space \( \mathbb{R}^{\text{nodes}(1)} \times \cdots \times \mathbb{R}^{\text{nodes}(N)} \) [30, Sec. 6.8].
3) They give rise to optimal control problems, which are amenable to dynamic programming formulations [65].
4) They allow for MPC formulations with closed-loop stability guarantees [28], [29].

The definition of \( \varrho_N \) in (33) allows to formulate the following optimization problem with decision variables \( v = [v^{(i)}]_{i \in \mathbb{N}_{[0, \mu - 1]}}, x = [x^{(i)}]_{i \in \mathbb{N}_{[0, \mu - 1]}}, \) and \( q = [q^{(i)}]_{i \in \mathbb{N}_{[0, \mu - 1]}} \).

**Problem 1:** Solve the optimal control problem

\[
\begin{align*}
\min & \ varrho_N(Z_1, \ldots, Z_N) \\
\text{s.t.} & \text{constraints (15) and given initial conditions } x^{(0)}, \xi^{(0)} \ldots \\
& \forall i_+ \in \mathbb{N}_{[1, \mu - 1]} \text{ and } i = \text{anc}(i_+).
\end{align*}
\]

Note that the cost function is the composition of a series of, typically, nonsmooth mappings. Such problems have been studied in the operations’ research literature and are typically solved by means of cutting plane methods, which allow the solution of problems with short prediction horizons and linear stage cost functions [31], [32]. Here, we employ the method introduced in [28] to decompose the nested conditional risk mappings and reformulate Problem 1 as an MIQCQP.

### C. Reformulation as an MIQCQP

In this section, we employ (32) to decompose the nested formulation stated above for the case of AVaR. By doing so, we will cast the overall MPC problem as an MIQCQP.

**Theorem 11 (Problem Reformulation):** Define the variables \( t^{(i)} \) for all non-leaf nodes \( i \) and the variables \( \xi^{(i)} \) for all nodes \( i_+ \in \mathbb{N}_{[1, \mu - 1]} \). Define

\[
\psi^{(i)} = t^{(i)} + \sum_{i_+ \in \text{child}(i)} \pi^{(i)} \xi^{(i)} \tag{36}
\]

for all non-leaf nodes \( i \), which is the cost in the minimization in (32). Let the underlying risk measure be the AVaR at level \( \alpha \in [0, 1] \). Then, with the additional decision variables \( t = [t^{(i)}]_{i \in \mathbb{N}_{[0, \mu - 1]} \setminus \text{node}(N)} \) and \( \xi = [\xi^{(i)}]_{i \in \mathbb{N}_{[1, \mu - 1]}} \), Problem 1 is equivalent to the following problem in the sense that both problems yield equal optimal values.

**Problem 2:** Solve the optimization problem

\[
\begin{align*}
\min_{v, x, q, t, \xi} & \psi^{(0)} \\
\text{s.t.} & \psi^{(i)} \geq 0 \\
& \alpha \psi^{(i)} \geq Z^{(i)} - t^{(i)} \chi_{\text{child}(i)}, \quad \text{if stage}(i) = N - 1 \\
& \alpha \psi^{(i)} \geq Z^{(i)} - \psi^{(i)} - t^{(i)} \chi_{\text{child}(i)}, \\
& \text{if stage}(i) < N - 1 \text{ constraints (15) and } \\
& \forall i_+ \in \mathbb{N}_{[1, \mu - 1]} \text{ and } i = \text{anc}(i_+).
\end{align*}
\]

**Proof:** Let us introduce a vector \( \Phi \in \mathbb{R}^{\mu - \text{nodes}(N)} \), which is defined over the non-leaf nodes of the scenario tree. In particular, we associate a value \( \Phi^{(i)} \in \mathbb{R} \) to every non-leaf node \( i \in \mathbb{N}_{[0, \mu - 1]} \setminus \text{nodes}(N) \). Similar to (20), we segment \( \Phi \) stage-wise into \( \Phi_i = [\Phi_i^{(i)}]_{i \in \text{nodes}(j)} \). Let us first define \( \Phi_{N - 1} \in \mathbb{R}^{\text{nodes}(N - 1)} \) over the set \( \text{nodes}(N - 1) \) as

\[
\Phi_{N - 1} = \rho_{N - 1}(Z_N). \tag{34a}
\]

\( \Phi_{N - 1} \) is the conditional value-at-risk at stage \( N - 1 \) and it corresponds to the innermost term in the nested multistage cost function (33) in Problem 1. Furthermore, let us define \( \Phi_j \in \mathbb{R}^{\text{nodes}(j)} \) over the set \( \text{nodes}(j), j \in \mathbb{N}_{[0, \mu - 2]} \) as

\[
\Phi_j = \rho_j(Z_{j + 1} + \Phi_{j + 1}). \tag{34b}
\]

The recursive definition (34) allows us to express the nested multistage risk measure (33) as

\[
\varrho_N(Z_1, \ldots, Z_N) = \rho_0(Z_1 + \rho_1(Z_2 + \cdots + \rho_{N-2}(Z_{N-1} + \Phi_{N-1}))) \ldots
\]

\[
= \rho_0(Z_1 + \Phi_1) = \Phi_0. \tag{35}
\]

Note that \( \Phi_{N - 1} \) in (34a) is composed of elements \( \Phi^{(i)}, \ i \in \text{nodes}(N - 1) \) and because of (32)

\[
\Phi^{(i)} = \rho^{(i)}(Z^{[i]}) = \min_{\xi^{[i]} \geq 0, \text{child}(i)} \psi^{(i)} \tag{36}
\]
where the minimization is carried out over the decision variables \( t^{(i)} \) and \( x^{(i)} = \{ x^{(i,j)} \}_{j \in \text{child}(i)} \).

The vector \( \Phi_j \) in (34b) comprises the elements \( \Phi^{(i)} \), stage\((i) = j \). For AvaR, as described in (32), they are

\[
\Phi^{(i)} = \rho^{(i)} (Z^{(i)} + \Phi^{(i)}) = \min_{\alpha \geq 0} \Psi^{(i)} \quad \text{s.t.} \quad \alpha x^{(i)} \geq Z^{(i)} + \Phi^{(i)} - t^{(i)} 1_{\text{child}(i)} \]

(37)

In light of (35), the above recursive procedure leads to the formulation of the following optimization problem.

**Problem 3:** Solve the optimization problem

\[
\min_{v,x,q,t} \Phi^{(0)} \\
\text{s.t.} \quad x^{(i)} \geq 0 \\
\alpha x^{(i)} \geq Z^{(i)} - t^{(i)} 1_{\text{child}(i)}, \quad \text{if stage}(i) = N - 1 \\
\alpha x^{(i)} \geq Z^{(i)} + \Phi^{(i)} - t^{(i)} 1_{\text{child}(i)}, \quad \text{if stage}(i) < N - 1 \\
\text{and given initial conditions } x(0), \delta_1(0). \\
\forall i \in \mathbb{N}_{[1,M-1]} \text{ and } i = \text{ance}(i_+) \]

In Problem 2, we substitute \( \Phi^{(i)} \) with \( \Psi^{(i)} \) in the cost function. Furthermore, because of Lemma 1.1, we can replace the constraint \( \alpha x^{(i)} \geq Z^{(i)} + \Phi^{(i)} - t^{(i)} 1_{\text{child}(i)} \) by the constraint \( \alpha x^{(i)} \geq Z^{(i)} + \Psi^{(i)} - t^{(i)} 1_{\text{child}(i)} \). This leads to Problem 2 completing the proof.

Since the operating cost of Section IV involves quadratic functions and binary variables, Problem 2 is an MIQCQP. As we will demonstrate in Section VII, this can be solved efficiently by standard software such as CPLEX or Gurobi.

### D. Risk-Averse MPC

The risk-averse optimal control problem is solved given the current measured state of the system and a scenario tree that describes the distribution of future available renewable infeed and demand over \( N \) stages. By solving Problem 2 at every time instant \( k \), we obtain a set of control actions \( v^{(i)} \) for \( i \in \mathbb{N}_{[0,M-1]} \setminus \text{nodes}(N) \) (see Fig. 3). Then, the control action associated with the root node of the tree, \( v^{(0)} \), is applied to the system. This procedure is repeated at every time instant \( k \in \mathbb{N}_0 \) in a receding horizon fashion leading to a risk-averse MPC scheme [49].

### VII. Case Study

In this case study, we aim to demonstrate the properties of the risk-averse model predictive control strategy introduced in Section VI-D. For the simulations, the MG in Fig. 7 is used. It comprises a storage, conventional, and renewable unit with the parameters from Table II as well as a load. The units and the load are connected by transmission lines that all have susceptance \( b_{ij} = -20 \text{pu} \) and conductance \( g_{ij} = 2 \text{pu} \). Hence, (12a) becomes

\[
\begin{bmatrix}
p_{c,1}(k) \\
p_{c,2}(k) \\
p_{c,3}(k) \\
p_{c,4}(k)
\end{bmatrix}
= \begin{bmatrix}
1 & 0 & 0 & 0 \\
0 & -1/3 & 1/3 & 0 \\
0 & 2/3 & 1/3 & 0 \\
0 & 1/3 & 2/3 & 0
\end{bmatrix}
\begin{bmatrix}
p(k) \\
p_2(k) \\
p_3(k) \\
w_4(k)
\end{bmatrix}
\]

Each line can transmit power between \(-1.3 \text{ and } 1.3 \text{ pu}\). Note that all values are given in per-unit (pu) [52].

All simulations were performed in MATLAB 2015a using the closed-loop setup shown in Fig. 1. In what follows, we will discuss the different parts of it, i.e., forecast, scenario reduction, MPC, and the MG plant model.

The wind speed and load forecasts were obtained with the seasonal ARIMA models from [20]. These were implemented using MATLAB’s Econometrics toolbox. The available power of the RES, i.e., of the wind turbine, was calculated from the wind speed forecast using the cubic approximation from [20].

The scenario tree was generated from a collection of 500 independent scenarios of load and available renewable power using [60, Algorithm 5]. The maximum number of children per node was chosen to be 6 for the root node, 2 for the nodes of stage 1, and 1 for all other stages. The tree was modified to include high-effect low-probability scenarios corresponding to the cases of very low available renewable power and very high load and vice versa. Hence, the scenario tree contains \(6 \cdot 2 + 2 = 14\) scenarios. Because of their very low probability, high-effect low-probability scenarios have minor influence on the stochastic case at \( \alpha = 1 \). However, for smaller values of \( \alpha \) that are close to zero, i.e., as we approach the worst case, their influence increases significantly as will be illustrated later.

For MPC, a prediction horizon of \( N = 8 \), a sampling time of \( T_s = (1/2) \text{ h} \), and a discount factor of \( \gamma = 0.95 \) were chosen. The different controllers were implemented using YALMIP R20180612 [66] and Gurobi 7.5.2 as a numerical solver. To speed up the computations, the results from the previous iteration were used as initial values to warm-start the optimization. Furthermore, the binary switch state of the conventional unit was relaxed for all stages greater than 3, i.e., \( \delta_1^{(i)} \in [0,1]^T \) for stage\((i) \geq 4 \) in the risk-averse MPC. The simulations in Section VII-A were performed on a computer with an Intel Xeon E5-1620 v2 processor at 3.70 GHz with 32-GB RAM. Here, the maximum solve time of Gurobi (excluding the time required by YALMIP to parse the problem)

\( ^b \) Corresponds to risk-neutral stochastic (expectation-based) MPC.

was below 7 s (see Table III). Considering a sampling time of \( T_s = (1/2) h \) [67], this is adequately fast.

In the plant model, the efficiency of the storage unit and an ac power flow model were considered to obtain more realistic simulation results. For the storage unit, the model described in Remark 2.5 with charging and discharging efficiency \( \eta_c^2 = \eta_d^2 = 0.92 \) and self discharge \( x^{sd} = 2 \cdot 10^{-3} \) pu h was used. For ac power flow, the model from Remark 2.7 was used employing the MATLAB function fmincon. Here, the line parameters posed earlier and voltages \( n_i = 1 \) pu, \( i \in \mathbb{N}_{[1,4]} \) were assumed. Note that this model was only used to simulate the MG plant and not the MPC problem formulations.

To compare the outcome of the different simulations, we introduce the average economically motivated cost

\[
\tilde{\ell}_o = \frac{1}{K} \sum_{k=1}^{K} \ell_o(v_s(k-1), v(k), z(k)) \tag{38a}
\]

over a simulation horizon \( K \) with \( \ell_o \) from (17). Using (19), we also introduce the average cost related to the stored energy

\[
\tilde{\ell}_s = \frac{1}{K} \sum_{k=1}^{K} \ell_s(x(k)) \tag{38b}
\]

Having described the simulation setup and the average costs, we can now discuss the simulation results. Here, we first provide a comparison of different controllers for a nominal simulation run. Then, we illustrate the properties of the risk-averse MPC in more detail in a sensitivity analysis.

A. Nominal Simulations

In what follows, the risk-averse MPC approach for different values of \( \alpha \) and a certainty-equivalent MPC approach where the mean value of the forecast is considered as the true value [10] are compared in closed-loop simulations. As shown in Table III, the certainty-equivalent approach leads to power constraint violations. These are caused by the discrepancy between data-based forecast and actual uncertain input, as well as the mismatch between the model in MPC and in the plant simulation and render the approach unsuitable for safe operation control. Therefore, it is not discussed further.

For the risk-averse approaches, it can be seen in Fig. 8 that with increasing \( \alpha \), energy is stored faster. Furthermore, the mean infeed from RES increases and the infeed of the conventional unit decreases (see Table III). These two effects contribute significantly to a decrease in the cost \( \tilde{\ell}_o \). Thus, with \( \alpha = 1 \), the cost \( \tilde{\ell}_o \) is reduced by 14% compared with \( \alpha = 0 \).

As the approach becomes more averse to risk with decreasing \( \alpha \), the average cost associated with the stored energy, \( \tilde{\ell}_s \), decreases. Two effects drive this decrease: 1) the handling of high-effect low-probability (HELP) scenarios in MPC and 2) the mismatch between the MG model in the plant simulation and that in MPC. However, simulations where the same model is used for the MG plant and MPC indicate that effect 1 plays the dominant role.

HELP scenarios represent extreme combinations of forecast values, which are very unlikely to happen. A misestimation of their probability can have a strong impact on the closed-loop performance. Risk-neutral stochastic MPC (\( \alpha = 1 \)) is agnostic to such misestimations and, therefore, cannot act proactively against misestimated HELP events. In closed-loop simulations, this is reflected by higher energy-related costs, \( \tilde{\ell}_s \), as probability distributions that do not follow the scenario tree are not considered. With decreasing \( \alpha \), ambiguity in the probability distribution is considered more leading to MPC formulations that account for misestimated probabilities of unlikely events. This leads to an increasing importance of unlikely scenarios, where the energy is outside the interval \([\bar{z}^{min}, \bar{z}^{max}]\), and results in control actions where more energy values are inside this interval leading to lower values of \( \tilde{\ell}_s \).

A comparison of the overall average cost, \( \tilde{\ell} = \tilde{\ell}_o + \tilde{\ell}_s \), shows that the lowest value \( \tilde{\ell} = 2.99 \) is achieved for \( \alpha = 0.5 \). This is about 6% lower than the overall cost for \( \alpha = 0 \) and \( \tilde{\ell} = 3.2 \), and about 26% lower than the overall cost for \( \alpha = 1 \) and \( \tilde{\ell} = 4.09 \).

The nominal simulations show that the risk-averse MPC approach provides an appropriate construction of the scenario tree leads to suitable operation strategies for islanded MGs. In practice, this translates into a desirable tradeoff between performance and robustness to uncertain probability distributions.

B. Sensitivity Analysis

To illustrate the performance of the risk-averse approach in the presence of inaccurate forecasts, a sensitivity analysis was carried out. In the analysis, 1000 closed-loop simulations were performed for the first three days, i.e., \( K = 144 \) simulation steps, of the scenario shown in Fig. 8. To demonstrate the robustness of the risk-averse approach to uncertainty in the probability distribution, we added noise to the uncertain input of the MG plant model. This way, occasional HELP events are artificially added to illustrate the positive effects of the risk-averse MPC approach. In the following analysis, we consider two different probability distributions of the additional noise: 1) constant offset in the mean value and 2) occasional offset that randomly occurs in 10% of the simulation steps.

1) Disturbance With Constant Offset: Here, a Gaussian noise term with nonzero mean and standard deviation equal to that of the ARIMA forecast training residuals is added to...
the wind speed and load time series. In particular, Gaussian noise with mean 0.048 pu and standard deviation 0.032 pu was added to the load and Gaussian noise with mean −0.795 (m/s) and standard deviation 0.53 (m/s) was added to the wind speed before the available wind power, \( w_r \), was obtained. The different scenarios of wind and load are shown in Fig. 9.

The resulting distribution of \( \tilde{\ell}_o \) is shown in Fig. 10. It can be observed that the mean of the economically motivated costs first decreases from \( \alpha = 1 \) to \( \alpha = 0.5 \) by 0.14%. Furthermore, the standard deviation of \( \tilde{\ell}_o \) significantly decreases from 0.019 for \( \alpha = 1 \) to 0.012 for \( \alpha = 0.5 \). Then, for \( \alpha = 0 \), the mean of \( \tilde{\ell}_o \) increases by 9.3% due to the increased conservativeness of the robust MPC approach. This shows that choosing \( \alpha < 1 \) can protect the system from HELP events, i.e., prevent extreme costs, and even reduce closed-loop costs. This is also reflected in the lower standard deviation of cost for smaller values of \( \alpha \). Furthermore, the energy related costs \( \tilde{\ell}_s \) decrease for smaller values of \( \alpha \). Thus, by choosing \( \alpha \) appropriately, the costs and the conservativeness of the control scheme can be tuned. This adds an important degree of freedom to the traditional design procedures of worst case (\( \alpha = 0 \)) and stochastic (\( \alpha = 1 \)) approaches.

2) Disturbance With Occasional Extreme Events: Here, the mean value of the additional noise was chosen different from zero for only 10% of the data points to model occasional extreme events. For the other data points, the mean of the additional noise was set to zero. The random nonzero offset in 10% of the cases was 0.096 pu for load and 1.589 (m/s) for wind speed. A standard deviation of 0.032 pu for load and 0.53 (m/s) for wind speed was considered for all cases based on the training residuals of the ARIMA forecast models. This led to the scenarios shown in Fig. 11.

As shown in Fig. 12, the energy related costs \( \tilde{\ell}_s \) decrease for lower values of \( \alpha \), yet, lower economically motivated costs \( \tilde{\ell}_o \) are not observed as \( \alpha \) decreases. However, the standard deviation of \( \tilde{\ell}_o \) decreases from 0.024 for \( \alpha = 1 \) to 0.007

Fig. 8. Power and energy of the MG using different controllers over one week of simulation with a sampling time of 1/2 h.

Fig. 9. 1000 scenarios of wind and load data used in sensitivity analysis with constant offset of 1.5 times the standard deviation.

Fig. 10. Results of sensitivity analysis with systematic error, i.e., constant offset in the mean value of the additional disturbance.

Fig. 11. 1000 scenarios of wind and load data used in sensitivity analysis with occasional extreme events.
for $\alpha = 0.0$, indicating that the average cost for operating the grid becomes less sensitive to inaccurate probability distributions with decreasing $\alpha$. This shows that the importance of HELP events can be explicitly parameterized by adapting $\alpha$. Additionally, for a given MG setup, the designer of the MPC has a tuning knob to strike a suitable tradeoff between the economically motivated $\bar{\ell}_0$ and the state related $\ell_s$.}

**VIII. CONCLUSION**

In this paper, we presented a risk-averse MPC strategy for islanded MGs with very high share of RES, which enables us to trade economic performance for safety by interpolating between worst case and risk-neutral stochastic formulations. The approach provides resilience with respect to misestimations of the underlying probability distributions of demand and available renewable infeed. Therefore, it is suitable for practical implementations, where these distributions are not known exactly or change over time. It also allows for the use of simple and, therefore, computationally less expensive scenario trees at the expense of operating with a slightly more conservative regime. Furthermore, the presented MPC scheme is able to protect MGs against high-effect low-probability events such as sudden drops of available renewable power or unexpected increase of demand. Finally, the proposed risk-averse MPC formulation can be cast as an MIQCQP, which can be solved by commercial solvers as indicated in Section VI.

For a large number of integer variables the problem complexity can potentially become prohibitive. In the future, we would like to look into this topic in more detail by considering MGs with more conventional and renewable units as well as scenario trees with a higher number of nodes.

Furthermore, as the operation regime is significantly influenced by the state of charge, we plan to consider more complex storage dynamics. Future work will also address chance constraints and decrease the solver time by devising parallelizable optimization algorithms [68] that can run on graphics processing units. Also, we plan to study statistically meaningful ways to choose the level of risk aversion [69].

**APPENDIX**

**Auxiliary Results**

**Lemma 12**: Let $\emptyset \neq \mathcal{X} \subseteq \mathbb{R}^n$ and $\emptyset \neq \mathcal{Y} \subseteq \mathbb{R}^m$ and for every $x \in \mathcal{X}$, $f(x, y)$ attains a minimum over $\mathcal{Y}$, i.e., $\min_{y \in \mathcal{Y}} f(x, y)$ exists. Then, the optimization problem

$$\min_{x \in \mathcal{X}, v} F(x, v)$$

s.t. $\min_{y \in \mathcal{Y}} f(x, y) \leq \beta$

with cost function $F : \mathbb{R}^n \times \mathbb{R}^m \rightarrow \mathbb{R}$ is equivalent to

$$\min_{x \in \mathcal{X}, v} F(x, v)$$

s.t. $y \in \mathcal{Y}$, $f(x, y) \leq \beta$.

**Proof**: As the two problems have the same cost function, it suffices to show that they have the same constraint sets. Therefore, we define $\mathcal{S} = \{x \in \mathbb{R}^n | \min_{y \in \mathcal{Y}} f(x, y) \leq \beta\}$ and $\mathcal{S}' = \{x \in \mathbb{R}^n | \exists y \in \mathcal{Y} \text{ such that } f(x, y) \leq \beta\}$.

Take $x \in \mathcal{S}$, i.e., $\min_{y \in \mathcal{Y}} f(x, y) \leq \beta$. Since the minimum exists, there is $y' \in \mathcal{Y}$ such that $f(x, y') \leq \beta$. Hence, $x \in \mathcal{S}'$, and consequently, $\mathcal{S} \subseteq \mathcal{S}'$.

Take $x \in \mathcal{S}'$, i.e., there is $y_0 \in \mathcal{Y}$ such that $f(x, y_0) \leq \beta$. Then, $x \in \mathcal{S}$ because $\min_{y \in \mathcal{Y}} f(x, y) \leq f(x, y_0) \leq \beta$, and consequently $\mathcal{S}' \subseteq \mathcal{S}$. This proves that $\mathcal{S}' = \mathcal{S}$.

Here, he is especially interested in model predictive operation control and time-series forecasting as well as distributed and decentralized control.

Jörg Raiss studied engineering cybernetics at Stuttgart University, Stuttgart, Germany, and control systems at the University of Manchester Institute of Science and Technology, Manchester, U.K., and the Ph.D. and Habilitation degrees from Stuttgart University.

He is the Chair for Control Systems with the Electrical Engineering and Computer Science Department, Technische Universität Berlin, Berlin, Germany, and he is also an External Scientific Member of the Max Planck Institute for Dynamics of Complex Technical Systems, Magdeburg, Germany. His main research interests include hybrid and hierarchical control, distributed cooperative control, and control of timed discrete-event systems in tropical algebras, with applications in chemical, medical, and power system engineering.

Carsten Reincke-Collon studied Electrical Engineering at Technische Universität (TU) Dresden, Dresden, Germany, and received the Diploma Engineering degree in 2005, and the Ph.D. degree *(summa cum laude)* in 2011.

He is currently the Director of Future Technology with the Global Products and Technology Unit, Aggreko plc, Berlin, Germany, a leading specialist provider of power, temperature control, and energy services. As an external doctoral candidate at the Laboratory of Control Theory, TU Dresden, his research focused on invariant feedback design for nonlinear (finite-dimensional) control systems possessing Lie symmetries employing a differential-geometric approach to symmetries of nonlinear systems. He joined Younicos AG, Berlin, Germany—a Berlin-based pioneer in battery storage systems and hybrids—serving in leading engineering roles and as a member of the Senior Management Team before the acquisition by Aggreko in 2017. His current research interests include solutions for optimal control of high-penetration microgrids.

Panagiota (Panos) Patrinos (M’13) received the M.Eng. degree, the M.S. degree in applied mathematics, and the Ph.D. degree in control and optimization from the National Technical University of Athens, Athens, Greece, in 2003, 2005, and 2010, respectively.

He is currently an Assistant Professor with the Department of Electrical Engineering (ESAT), KU Leuven, Leuven, Belgium. In 2014, he was a Visiting Assistant Professor with the Department of Electrical Engineering, Stanford University, Stanford, CA, USA. He has held post-doctoral positions at the University of Trento, Trento, Italy, and IMT Lucca, Lucca, Italy, where he became an Assistant Professor in 2012. His current research interests include the interface of optimization, learning, and control with a broad range of applications, including autonomous vehicles, smart grids, water networks, aerospace, multi-agent systems, signal processing, and machine learning.
